Statistical Learning and Prediction

Marjolein Fokkema

Leiden University m.fokkema@fsw.leidenuniv.nl

This Course

- New methodology for data analysis
- Same models, different focus
- Statistics and Machine Learning: Statistical Learning

Schedule

- 1. Tue, 11:00-13:00 Introduction, bias-variance trade-off (MF).
- 2. Tue, 14:00-16:45 Classification, resampling, cross validation (TW)
- 3. Tue, 17:00-18:15 Regularization, model selection (TW)
- 4. Wed, 10:00-12:00 Unsupervised learning (TW)
- 5. Wed, 13:00-18:00 Non-linear methods (trees, splines, SVMs) (MF)

Statistical Learning

Vast set of tools for understanding data.

- − Supervised: $Y \leftarrow f(X_1, ..., X_p)$; predict Y on the basis of X
- Unsupervised: X_1, \ldots, X_p ; finding structure in X (underlying dimensions/groups)

Statistical Learning

• The linear regression model

$$Y = f(X_1, \dots, X_p) + \epsilon$$
$$= \beta_0 + \beta_1 X_1 + \dots + \beta_p X_p + \epsilon$$

can be used for explanation and/or prediction.

- Explanation: understanding how the X's are related to Y; possibly causally.
- <u>Prediction</u>: if we have new observations with known values of *X*'s, what is the expected (predicted) value of *Y* and how accurate are these predictions?

Explanatory Regression

Suppose we have data and obtained estimates:

$$\hat{y}_i = 2 + 0.5x_{i1} + 1.5x_{i2}$$

- Estimated coefficients indicate magnitude of the effects, standard errors indicate variability of estimates.
- Use statistical tests for deciding whether the explanatory variables really affect the response, given the other variables.
- Adequate estimation of coefficients $(\hat{\beta})$ is assumed crucial: Accurate estimates = unbiased estimates! That is:

$$\mathbb{E}[\hat{\beta}] = \beta$$

Explanatory Regression

Unbiased estimates can be obtained with e.g., OLS:

$$\hat{\beta} = \arg\min_{\beta} \left(\sum_{i=1}^{N} (y_i - f(x_i, \beta))^2 \right)$$

• "From a Bayesian perspective, the principle of unbiasedness is reasonable in the limit of large samples, but otherwise it is potentially misleading" (Gelman et al., 1995)

Predictive Regression

• Suppose we have data and have obtained estimates:

$$\hat{Y} = 2 + 0.5X_1 + 1.5X_2$$

- Suppose we have a new observation $x_0 = \begin{bmatrix} 2 & 3 \end{bmatrix}$
- With these values we can predict Y, i.e., $2 + 0.5 \times 2 + 1.5 \times 3 = 7.5$
- We do not care to recover parameters that generated the data, but want to obtain a model that yields as accurate as possible \hat{Y} .
- I.e., minimize

$$\mathbb{E}(\hat{Y} - Y)^2$$

Exercise 1: Bias can be beneficial

• Generate some training observations in R:

```
set.seed(1)
x <- runif(50, min = -3, max = 3)
epsilon <- rnorm(50)
y <- 0.1*x + epsilon</pre>
```

• Combine the observations into a training dataset:

```
train_dat <- data.frame(x, y)</pre>
```

• Estimate $\hat{\beta}_{OLS}$ on the training observations (exclude the intercept from the model):

```
beta_OLS <- coef(lm(y \sim 0 + x, data = train_dat))
```

• Generate 1,000 new observations from the same distributions as above. Combine the observations into a test dataset (test_dat).

• Generate a range of shrinkage factor values:

```
s < - seq(0, 1, by = .1)
```

- Compute predictions for the test observations, but apply shrinkage to the OLS coefficient: $\hat{Y} = X \cdot s \cdot \hat{\beta}_{OLS}$
 - You thus generate predictions for the test observations 11 times: once for each value of the shrinkage factor *s*.
- For each value of *s*, compute MSE (mean squared prediction error) on the test observations.
- Plot the test MSE values as a function of shrinkage factor *s*. Is shrinkage beneficial for prediction?

Exercise 1 - Continued

- To eliminate effects due to chance fluctuations, repeat the above experiment 100 times, and plot the average MSE (over the 100 replications) as a function of shrinkage *c*.
- Plot the distribution of estimated coefficients against the values of *s*. (Hint: use function boxplot)
- Repeat above with increased training sample size: N = 100.
- Repeat above for twice as strong an effect (i.e., $Y = .2X + \epsilon$).
- Describe how optimal amount of shrinkage is affected by sample and effect size.

Predictive Regression

- Traditional statistical textbooks focus on obtaining *unbiased* estimates (e.g., OLS, ML).
- (Modern) statistical learning accepts biased parameter estimates as long as *variance* decreases more than *squared bias* increases:

Predictive perspective: Bias-variance trade-off

- We have a probability distribution P^* , from which we draw a sample \mathcal{T} of size N
- Let f_B be Bayes optimal f (unknown, depends on P^*)
- Let $\bar{f}(X) = \mathbb{E}_{\mathcal{T}}[\hat{f}(X)]$
- Aim is to minimize *expected prediction error*:

$$\mathbb{E}_{\mathcal{T}}[\text{EPE}(\hat{f})] = \mathbb{E}_{X}[Var(Y|X)] +$$

$$\mathbb{E}_{X}[(f_{B}(X) - \bar{f}(X))^{2}] +$$

$$\mathbb{E}_{\mathcal{T}}\mathbb{E}_{X,Y}[(\hat{f}(X) - \bar{f}(X))^{2}]$$

• EPE = irreducible error (or σ^2) + bias² + variance

Population: Non-linear Regression

Often we fit a linear model, assuming that the conditional means in the population lie on a straight line.

This assumption is most likely false! Why does it often work so well?

Excercise 2: Under- and overfitting with polynomial regression

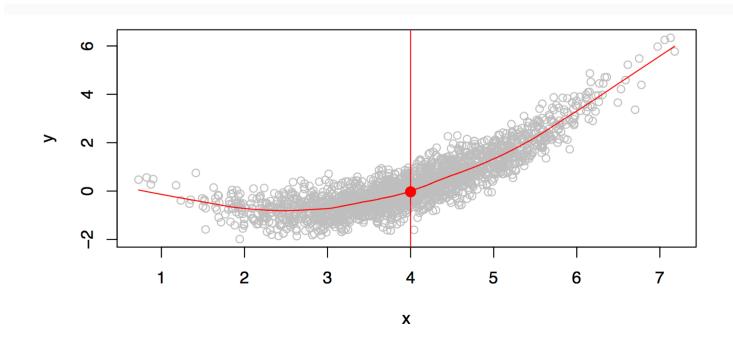

• Generate a training and test set, each with n = 50, with a single predictor which has a non-linear effect on the response:

```
set.seed(42)
n <- 50
x <- runif(n, min = -5, max = 5)
y <- x + 8*sin(x/2) + rnorm(n)
train <- data.frame(x, y)
x <- runif(n, min = -5, max = 5)
y <- xtest + 8*sin(xtest/2) + rnorm(n)
test <- data.frame(x, y)</pre>
```

Excercise 2 - Continued

- Fit polynomial regression models to the training data of degree 1 trough 15, make predictions on the test set and compute the prediction error for each degree.
 - Hint: Use functions lm, poly, and a for loop. E.g.: $lm(y \sim poly(x, degree = 3))$
- Plot the test MSE as a function of the degree of the polynomial.
- If time permits, create a plot which shows the training observations, and fitted curves for the degree 1, 2, 3 and 15 polynomials.

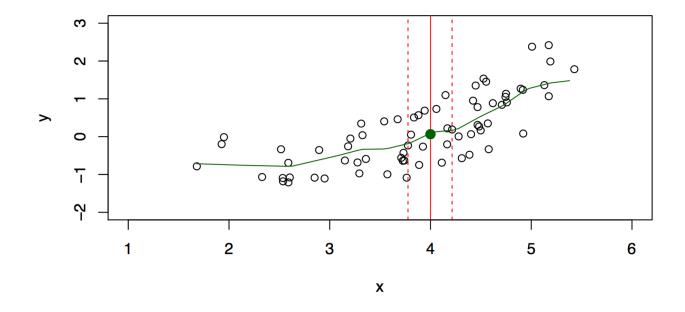

Population: Non-linear Regression

The regression line in the <u>population</u> combines the conditional means at each point x

Sample data

Using sample data, we want to obtain an estimate $\hat{f}(X)$ of f(X).

- Due to sparsity, cannot estimate a conditional mean at all points X = x.
- \bullet Thus, take a small neighbourhood around X = x and take

neighbourhood mean as predicted value, i.e. *nearest neighbour* averaging.

• The larger the neighbourhood, the larger the bias and the smaller the variance.

Multiple Predictor Variables

With multiple predictors the observations are further spread out through the space:

- Nearest neighbours might not be near at every point
- Flexible models become very wild
- This is known as the *curse* of dimensionality
- More structure in *f* is needed
- How can we impose structure?

Exercise 3: Curse of dimensionality

• Generate a dataset with p=10,000, N=100 and $X \sim \mathcal{N}(\mathbf{0},\mathbf{I})$: p <- 10000

```
N <- 100
set.seed(42)
```

 $X \leftarrow matrix(rnorm(p*N), ncol = p, nrow = N)$

- Create a histogram of the Euclidian distances between all points in the dataset. First, only use the first column of X to compute the distances (i.e., p = 1), then use the first two columns (i.e., p = 2), and so on for $p \in \{1, 2, 10, 100, 1000, 10000\}$.
 - Hint: use functions dist to compute the distances of the observations in X, use function hist to create a histogram.

Specify argument xlim for each histogram, to make sure the value of 0 is included on the x-axis.

• Are the nearest neighbours near in 1-dimensional space? In 2-dimensional space? In 10-, 100-, 1000-dimensional space?

Evaluating predictive accuracy: Numeric outcome

• Mean squared error (MSE):

$$\frac{1}{N_{test}} \sum_{i=1}^{N_{test}} (y_i - \hat{y}_i)^2$$

• Mean absolute error (MAE):

$$MAE = \frac{1}{N_{test}} \sum_{i=1}^{N_{test}} |y_i - \hat{y}_i|$$

Classification

Response variable Y may be a categorical variable with categories C = 1, ..., k, ..., K.

Again, we want to predict response *Y* based on predictors *X*:

- Can directly construct a classifier $\hat{f}(X) = C(X)$ that assigns a predicted category from C based on X.
- Can construct a function $\hat{f}(X)$ that provides conditional probabilities: $\hat{p}_k(X) = Pr(Y = k|X = x)$.

Then Bayes classifier assigns C(X) = k if $\hat{p}_k(x) = \max{\{\hat{p}_1(x), \dots, \hat{p}_K(x)\}}$

Evaluating predictive accuracy: Classification

• Misclassification rate:

$$\frac{1}{N_{test}} \sum_{i=1}^{N_{test}} I(y_i \neq \hat{y}_i)$$

• Brier score:

$$\frac{1}{N_{test}} \sum_{i=1}^{N_{test}} (y_i - \hat{y}_i)^2$$

• Cross-entropy:

$$-\frac{1}{N_{test}} \sum_{i=1}^{N_{test}} [y_i \cdot \log(\hat{y}_i) + (1 - y_i) \cdot \log(1 - \hat{y}_i)]$$

Exercise 4: Flexibility and predictive performance

For each of parts (a) through (d), indicate whether we would generally expect the performance of a flexible statistical learning method to be better or worse than an inflexible method:

- a) Sample size *N* is extremely large, and the number of predictors *p* is small.
- b) The number of predictors *p* is extremely large, and the number of observations *N* is small.
- c) The relationship between the predictors and response is highly non-linear.
- d) The variance of the error terms, $\sigma^2 = Var(\epsilon)$, is extremely high.
